Abstract

A striking range of individual differences has recently been reported in three different visual search tasks. These differences in performance can be attributed to strategy, that is, the efficiency with which participants control their search to complete the task quickly and accurately. Here we ask if an individual's strategy and performance in one search task is correlated with how they perform in the other two. We tested 64 observers and found that even though the test-retest reliability of the tasks was high, an observer's performance and strategy in one task was not predictive of their behaviour in the other two. These results suggest search strategies are stable over time, but context-specific. To understand visual search we therefore need to account not only for differences between individuals, but also how individuals interact with the search task and context.

Stable individual differences in strategies within, but not between, visual search tasks

Introduction

As is common in cognitive psychology, most visual search literature has focused on how the average participant performs in the task, despite it being well known that there is a great deal of variability between one subject and the next. From Treisman's work on Feature Integration Theory (Treisman & Gelade, 1980) to the latest incarnation of the Guided Search Model (Wolfe, Cain, Ehinger, & Drew, 2015), we have a good understanding of what makes particular objects easier or harder to find. However, these theories and models have neglected the question of why some observers find visual search so much harder than others. These differences can emerge from several different sources of variation: tiredness (Mackworth, 1948), information-processing ability, speed-accuracy trade-off, motivation, visual impairments (Nowakowska, Clarke, Sahraie, & Hunt, 2016), and search strategies (Boot, Kramer, Becic, Wiegmann, & Kubose, 2006). Although their existence has previously been noted (Mackworth, 1948), a rigorous examination of individual differences in visual search is a challenge that has not been taken up by many researchers, and questions about their impact and stability remain relatively under-explored.

Here we focus on one source of individual differences in visual search: strategy. By strategy we mean a collection of search behaviours from which all observers can freely choose. Examples include adopting a systematic left-to-right and top-to-bottom strategy (Gilchrist & Harvey, 2006), or prioritizing locations that, based on knowledge or context, are more likely to contain the target (Wolfe et al., 2015). A striking example of the effect of strategy is given by Boot et al. (2006). They asked participants to monitor a cluttered display for an object changing colour or suddenly appearing. Large individual differences were found with respect to the number of saccades participants made while monitoring the stimulus, which was negatively correlated with detection performance.

Eye movement strategies have also been shown to be an important source of individual differences in visual search efficiency. Nowakowska, Clarke, and Hunt (2017)

designed a simple search paradigm to discriminate between optimal (Najemnik &
Geisler, 2008) and stochastic (Clarke, Green, Chantler, & Hunt, 2016) search strategies.
Participants searched through arrays of line segments (Figure 4) arranged such that
those on one side of the display all had a very similar orientation (homogeneous), while
those on the other side had higher variance (heterogeneous). This meant that targets
appearing on the homogeneous side were highly salient, while targets on the
heterogeneous side were harder to find. The optimal strategy here is to search the
heterogeneous half, as targets on the homogeneous side can be detected with peripheral
vision. We will refer to this paradigm as the Split-Half Line Segment task (SHLS).
Some participants searched the displays near optimally, but others carried out strategies
counter to this, failing to even match the performance of the stochastic searcher. The
degree to which participants made saccades in line with the optimal search strategy was
strongly correlated with the speed of their search. A related version of this paradigm
has been used in research investigating eye movement strategies in response to
(simulated) hemianopia (Nowakowska et al., 2016; Nowakowska, Clarke, Sahraie, &
Hunt, 2018), with similar conclusions: the full spectrum of individual differences in
strategy was observed. It is therefore not possible to conclude whether optimal or
stochastic models better describe search without first explaining individual variability.

A similar range of strategies, from random to near-optimal, has been found by
Irons and Leber (2016) with the Adaptive Choice Visual Search (ACVS) paradigm.
This paradigm involves stimuli made up of small coloured boxes (red, blue, green and a
fourth colour that varies from red, through purple, to blue and back again) with
numerals written inside them (Figure 4). The target is a defined as a red or blue box
containing one of four numerals (e.g., 2-5), and on each trial one target of each colour is
present. The participant's task is to find one of either target as quickly as possible and
report the numeral. On trials in which the fourth colour is red (or close to red),
participants should search through the blue boxes and report the blue target, as there
will be fewer distracters. As the fourth colour changes to through purple to blue,
participants should update their strategy and search for the red target. The results

showed that participants varied substantially along two key dimensions: how frequently they used the more effective target colour to search (varying from chance performance to near optimal), and how often they changed between colours. Further work (Irons & Leber, 2018) has shown that these differences are stable over time (between one and ten days) with test-retest correlations of around $r = 0.83$ (95% CI $= [0.72, 0.90]$) for optimal choices.

Another example of differences in search strategy comes from the foraging literature (Jóhannesson, Thornton, Smith, Chetverikov, & Kristjánsson, 2016; Kristjánsson, Jóhannesson, & Thornton, 2014). In this context, foraging tasks involve searching for multiple targets on each trial. Participants were asked to search through a set of items from four categories, with two categories classed as targets. In the conjunction condition (searching for red-horizontal and green-vertical line segments among red-vertical and green-horizontal distracters), most observers searched in runs, finding all the targets of one target category, and then switching and finding the targets in the other category. This strategy has previously been observed in animal foraging (Dawkins, 1971), and suggests holding one complex target template in mind at a time is a better strategy than switching templates. However, a sub-set of participants, termed 'super-foragers', were able to change between search target categories with no cost to performance. While test-retest reliability has not been measured explicitly for the foraging paradigm, the task was used as a measure to assess the effect of a six day mindfulness retreat on cognitive performance (Hartkamp & Thornton, 2017). From a re-analysis of these data, we can estimate that the test-retest reliability for the mean run length is $r \approx 0.7$ for the feature condition and $r \approx 0.88$ for the conjunction search.

Previous research has investigated the relationship between these behaviours to psychometric measures, but to date, these differences have not shown strong correlations with other attributes. Irons and Leber (2016, 2018) found no evidence of a correlation between the proportion of optimal choices made by observers in the ACVS paradigm and measures of visual working memory; trait impulsivity; novelty seeking; need for cognition; and intolerance of uncertainty. Similarly, the differences in foraging

behaviour are not accounted for by working memory or inhibitory control (Jóhannesson, Kristjánsson, & Thornton, 2017).

A common theme emerging from these studies is the observation that individual strategies vary in their degree of effectiveness or optimality. However, "visual search" encompasses a wide range of tasks, each tapping into a different aspect of behaviour (e.g. feature-based attention, information sampling). The aim of the present study is to investigate the extent to which individual differences are stable across different visual search paradigms. Does it make sense to talk about 'super-searchers' who show above-average performance in a range of search tasks (analogous to the 'super-recognizers' of the face-recognition literature (Russell, Duchaine, & Nakayama, 2009))? As a secondary question, we will measure the test-retest reliability of the differences found in the SHLS paradigm, and compare it with existing estimates of reliability for ACVS and MCFT.

Methods

The methods and planned analysis for this study were registered on the Open Science Framework[1] before data collection started.

Participants

64 students with normal or corrected-to-normal vision from the University of Aberdeen took part in this study[2]. Participants were compensated for their time with either course credit or £15. All participants gave informed consent. The study was approved by the University of Aberdeen Psychology Ethics Committee.

Sample size was determined in part by a power analysis, and in part by counter-balancing. With $n = 64$ participants, correlations with $r > 0.34$ with $\alpha = 0.05$, $\beta = 0.80$ between the different visual search paradigms can be detected. The sample is therefore of sufficient size to detect relatively small correlations.

---

[2] data from an additional 11 participants was discarded due to being recorded with an inappropriate screen resolution. Another participant was excluded due to colour blindness.

Materials and Procedures

The study consists of three paradigms from the visual search literature in which large individual differences have been found (Irons & Leber, 2016; Kristjánsson et al., 2014; Nowakowska et al., 2017). Example stimuli can be seen in Figure 4. A brief overview of each paradigm is given below, with full details in *supplementary materials.* The three tasks were completed over two sessions, approximately one week apart. The SHLS was run in both sessions. The order in which participants completed the tasks was counter-balanced. There are 16 different possible orders of tasks/conditions; four participants completed each order for a total of 64.

The display was presented on a 17-inch CRT monitor with a resolution of 1400×1050 ($n = 40$) or 1600×1200 ($n = 24$). Stimulus generation, presentation and data collection were controlled by MATLAB and the psychophysics and eyelink toolboxes (Brainard, 1997; Cornelissen, Peters, & Palmer, 2002) run on a Powermac. Participants sat ≈ 47cm from the screen.

Split-half Line Segments.   Stimuli consisted of arrays of black oriented line segments against a grey background. The target was oriented 45° clockwise, while the distractor items had a random orientation with a mean of 45° anti-clockwise. The variance was low (18°) on one half of the display to create a homogeneous texture, and high (95°) on the other side to create a heterogeneous texture. When the target is present on the homogeneous half, it can be easily be detected with peripheral vision, but when it is in the heterogeneous half, it is much harder to detect (this was verified in Nowakowska et al. (2017)). There were 160 trials in total and homo- and heterogeneous sides of the display were randomly varied from trial to trial. The dominant eye position was recorded using a desktop-mounted EyeLink 1000 eye tracker (SR Research, Canada).

This paradigm was carried out twice, once in each testing session, to give us an estimate of how consistent participants are in their search strategy over time.

Adaptive Choice Visual Search.   Each search display was composed of red, blue, green and variable-coloured small squares arranged in three concentric rings

around fixation. Variable distractors changed colours from trial-to-trial according to a 24 trial cyclical pattern: the distractors would be red for five trials, then across a period of seven trials, they would gradually change colour from red to blue. The variable distractor would then be blue for five trials, and then gradually transition back to red.

A white digit appeared inside each square. Participants were informed that two targets - a red square and a blue square each with a digit between 2 and 5 - were embedded in every search display. The two target digits were always different, to enable us to distinguish the chosen target. The remaining red, blue and variable squares all contained digits between 6-9. Green squares could contain any digit between 2-9. The location of the targets and distractor within the search display were randomized on each trial. Participants were only required to find one target on each trial, and they were free to search for either one.

Mouse Click Foraging Task.   In the feature foraging condition, search displays contained small red, green, yellow and blue circles. For half of the participants, targets were red and green circles, and for the other half of participants, targets were blue and yellow circles. Participants were asked to collect all of the targets within a trial by using the mouse to click on each target. Clicking on a target caused it to disappear from the display. If the participant clicked erroneously on a non-target, the trial immediately ended and a replacement trial began. The conjunction foraging task was the same, except search displays were composed of both circles and squares. For half of the participants, the shapes were red and green, and for the remaining participants the shapes were blue and yellow. Targets were defined by conjunctions of colour and shape (e.g., red squares and green circles, with red circles and green squares as distractors). The assignment of targets and distractors was assigned at random for each participant. The procedure was otherwise identical to the feature foraging task.

Results

Replication of each task

A brief summary of participants' behaviour is given below. More time is spent on SHLS as the test-retest validity of it has not previously been assessed. Further analysis and details can be found in the *supplementary materials*.

Split-half Line Segments. Our results are consistent with the original SHLS study (Nowakowska et al., 2017): we find a large range of individual differences in search reaction time and accuracy (see Figure 1). These differences are stable across the two sessions, with Pearson's $r \in [0.71, 0.89]$ (95% CI.) for accuracy in finding hard targets. We get similar scores for the correlation in reaction times between sessions a and b for hard targets, ($r \in [0.54 - 0.81]$), easy targets ($r \in [0.52 - 0.80]$) and target absent trials ($r \in [0.66 - 0.86]$).

(a)   (b)   (c)   (d)
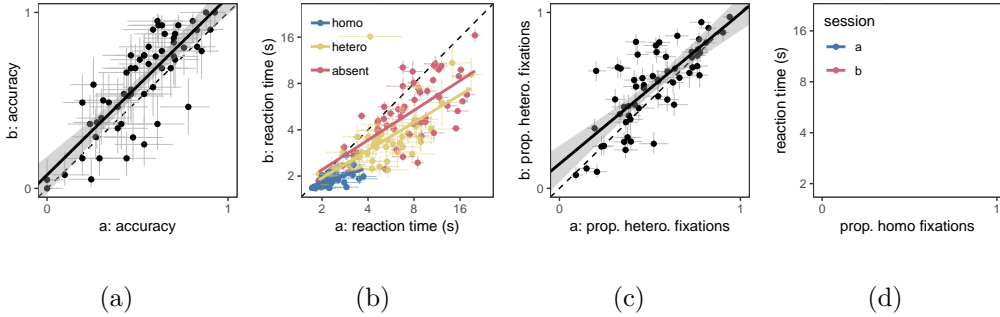

Figure 1. Correlation between the two sessions of the SHLS paradigm for (a) accuracy (TP-heterogeneous trials only); (b) reaction times and (c) search strategy (TA trials only). (d) Initial search strategy correlates with reaction times in both sessions. Each point represents a participant and the error-bars indicate 95% confidence intervals.

We can also look at the initial search strategies adopted by our participants 1(c, d). Again, we see large and stable individual differences across the two sessions (test-retest $r \in [0.63, 0.86]$ for the proportion of the first five saccades to the heterogeneous half of the display for target absent trials). More importantly, as with (Nowakowska et al., 2017), we see that the search strategies give a good correlation with reaction times in both session a, $r \in [0.52, 0.82]$ and session b, $r \in [0.50, 0.80]$.

Adaptive Choice Visual Search. We measured an individual's strategy as the percent of plateau trials in which the individual chose the optimal target (i.e., the target with the fewest distractors: When the variable distractor was red, the optimal choice was blue, and vice versa). The results for the ACVS were consistent with previous findings (Irons & Leber, 2016, 2018). We can clearly see from figure 2(a) that there are individual differences in the proportion of optimal targets reported (range 33.62% - 100.00%, $\bar{x} = 59.15$, $s = 16.54$) and the mean ($\log_2$) reaction times (range 1.90 - 4.80 seconds). As with the SHLS task, the degree to which participants follow the optimal strategy is correlated with reaction times ($r \in [-0.65, -0.25]$).

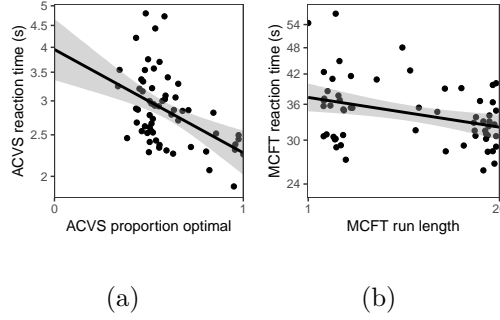

(a) (b)

Figure 2. Correlation between strategy and reaction times for (a) ACVS and (b) MCFT. Each point represents a participant.

Mouse Click Foraging Task. The main measure of interest was average run length per trial in the conjunction condition, with a run defined as a succession of one or more of the same target type, which was followed and preceded by the other target or no target. The average run length was the mean number of target selections in a run. The multiple-target foraging results were in line with previous findings (Jóhannesson et al., 2016; Kristjánsson et al., 2014), with shorter run lengths for feature foraging ($\bar{x} = 3.16$, $s = 3.14$) than conjunction foraging ($\bar{x} = 11.73$, $s = 7.09$). This suggests more frequent foraging for multiple targets concurrently when those targets were defined by features than by conjunctions. Figure 2(b) depicts the individual differences in terms of run length and the correlation with reaction time ($r \in [-0.55, -0.10]$).

Correlations Between Tasks

We have successfully replicated the previous findings around individual differences in visual search strategy in each of the three tasks. Furthermore, the SHLS task has been shown to have good test-retest reliability, similar to that of the ACVS and MCFT tasks. Given this, we can report the extent to which an individual's performance in one of the tasks predicts performance in the other two.

The results show that the correlations between the strategy metrics in the three tasks (Figure 3) are weak. Perhaps even more surprisingly, there is also little evidence for meaningful correlations between reaction times in the different tasks. Even if we optimistically take all data together as suggesting a robust correlation in reaction times from one task to another, the mean correlation over the three tasks is only $r = 0.2$, implying that this correlation accounts for $R^2 = 0.04 = 4\%$ an individual's performance.

Figure 3. The between- and within-task correlations for the three different search tasks. The bars indicate the 95% confidence intervals for Pearson's correlation coefficient. Blue bars represent test-retest scores for each task for reaction times (rt), optimality (opt) or run length (rl). Yellow bars indicate how well the strategy measures predict reaction times, while the red bars show that performance in one task is not a good indication of performance in another, either for reaction times or strategy.

Discussion

We successfully replicated the wide range of individual differences in strategy and performance that had previously been observed in each of these three visual search paradigms, with a larger sample size than the original experiments. Surprisingly, however, the between-paradigm correlations give $R^2 \approx 0.04$, and this is a generous interpretation that would fail to pass the usual criteria for null hypothesis significance testing. Knowing how one person will behave in one of these paradigms tells us very little about how they will perform in the others. This can be contrasted with the relatively high test-retest correlations of all three of the tasks individually, which range from 0.58 to 0.92.

There are many reasons why two measurements might be uncorrelated, such as range restriction or measurement noise. The test-retest correlations on each of the individual visual search tasks rule out many of these alternatives, leaving a true absence of shared variance between these tasks as a likely explanation. One might have expected reaction time to be at least modestly correlated from one search task to the next, even in the absence of correlations in strategy, as a general factor like an individual's speed-accuracy trade-off, motivation or conscientiousness might lead to better or worse overall performance across all the tasks. However, what we did observe were high correlations between our measures of strategy and reaction time within each task, suggesting our strategy metrics determine a large proportion of search performance, and reinforcing the interpretation that an individual who is strategic in one task is not necessarily strategic in the others.

Although the tasks in this experiment all have visual search in common, they also have unique aspects that appear to have resonated with particular individuals' strengths, and not others. Our definition of a successful strategy in the SHLS task was fixating the locations that provide new information. In the ACVS task, a successful strategy meant appropriately altering search goals to match changes in the environment. In the MCFT task, success involved minimizing cognitive load by minimizing target switching. Each of these tasks clearly taps into unique aspects of

visual search strategies, and performance on one has little bearing on the others.

Individual differences pose a challenge for efforts to devise a comprehensive model of visual search. Our understanding of the mechanisms of visual search is based predominantly on experiments that systematically vary details of the search task and measure their effects on averaged performance. This approach has led to important insights, for example, about the kinds of visual features that can guide attention (e.g. (Treisman & Gelade, 1980; Wolfe, 2007); how attentional control settings filter distractors (e.g. (Folk, Remington, & Johnston, 1992; Yantis & Egeth, 1999)); and biases in attention, such as a bias towards unexplored locations (e.g. (Klein, 2000)). For all three of the experiments included in the current study, however, the average performance would be highly misleading, as it would describe very few of the individuals' performance. In the original SHLS study (Nowakowska et al., 2017), for example, the original aim of the experiment was to assess whether search behaviour could be better described by an optimal (Najemnik & Geisler, 2008), versus a stochastic (Clarke et al., 2016), model. Considering only the average search performance, the stochastic model was a good explanation. Underlying that average performance, however, was a large spectrum of search behaviour, replicated here, some of which would be clearly categorized as optimal, and some as stochastic, and some as neither. The original question needed to be refined into new question: for whom is search optimal and for whom is it stochastic? The current findings add even further challenges for researchers interested in understanding visual search, by suggesting we need to account not only for individual differences, but also for the interaction of a given individual with a particular search context.

We view these findings not as a discouraging result, but as thought-provoking and exciting. Vogel and Awh (Vogel & Awh, 2008) argued that studying individual differences in cognitive psychology (in their case, working memory) provides valuable insight to containing potential theories of the underlying cognitive mechanisms. Our results suggest that context and structure of the task also needs to be taken into account. Understanding how an individual's behaviour varies across different search

tasks can lead to the development of a more comprehensive theory of search.
